Abstract
Cassava is an important crop in coastal Kenya commonly harvested at 12 months after planting but earlier during food shortages. There is limited information that addresses the effect of early harvesting on root quality especially for newly released varieties. Varieties Tajirika, Karembo and Kibanda Meno (roots) were harvested at different ages from Research Centres, studied for nutritional quality and hydrogen cyanide levels for safe utilization. Results showed significant (p < 0.05) interaction effect of varieties and crop age on studied nutrients. Karembo and Tajirika had peak dry matter of 43.42% and 41.42% respectively at 12 months while the peak for Kibanda Meno was 44.99% at 9 months. Mean starch content varied with variety; Karembo (91.3%), Kibanda Meno (93.4%), and Tajirika (85.5%). Karembo and Tajirika had peak carbohydrates at 12 months while the peak for Kibanda Meno was at 9 months. Mean starch content varied with variety; Karembo (91.3%), Kibanda Meno (93.4%), and Tajirika (85.5%). Vitamin C was highest at 6 months for Karembo (6.4 mg/100g) and Kibanda Meno (66 mg/100g). Tajirika had highest vitamin C (7.0 mg/100g) at 9 months. Iron was peak at 3 months for Karembo (3.63 mg/100g) and Tajirika (5.33 mg/100g) but at 9 months for Kibanda Meno (7.12 mg/100g). Peak Zinc was 2.1 mg/100g for Karembo at 6 months while for Kibanda Meno (1.94 mg /100g) and Tajirika (1.75mg /100g) at 12 months. Hydrogen cyanide increased from 8.6 to 9.3 mg/kg in  Karembo between 9 and 12 months, it decreased from 7.8 to 5.2 mg/kg and from 5.1 to 4.5 mg/kg in Tajirika and Kibanda Meno, respectively. Harvesting of cassava roots should be staggered across crop ages to maximize on peaks of different root nutrients and processing is important.

Keywords: Cassava varieties, roots, nutrients, hydrogen cyanide, months after planting

1. Introduction
Cassava remains an important food crop in the coastal region of Kenya, ranked second after maize FAOSTAT, (2013). The crop has successfully been incorporated into many farming systems FAO, (2005); FAO, (2005). This has made cassava to be very popular among smallholder farmers. It is one of the traditional crops, and it is significant in coastal dishes and menus Githunguri, (1995). The coast region experiences unfavorable temperatures and rainfall but cassava thrives in sub optimal conditions. This makes it the only food crop of hope to farmers. It therefore has the potential to provide food to rural households during harsh weather conditions when other food crops have failed Imungi et al. (1989).

In 2008, the Kenya Agricultural Research Institute released eight improved cassava varieties for production and consequent utilization by farmers in coastal Kenya KARI, (2009). These varieties were bred for high yield, pest and disease resistance. Post-harvest issues were hardly considered. This is however a common phenomenon where breeders give more emphasis on agronomic traits for targeted varieties with limited studies on postharvest taken in to consideration Bechoff et al. (2018). This created information gaps that need to be addressed. For example, the new varieties still need to be studied to determine their nutrient build up trends- a recommendation documented by Gethi et al. (2009).

Cassava roots are recommended to be harvested at 12 months after planting Muli et al. (2008); Nhassico, (2008) but this only applies under ideal food security situations. Under food shortage, farmers start harvesting cassava as early as three or six months after planting when they notice cracks on the ground FAO, (2005).

Cassava breeders focus on agronomic traits Bechoff et al. (2018) that include disease and pest resistance and improvement of yields in selected varieties KARI, (2009) report proves the same as the newly released varieties were reported to have been evaluated in the national performance trial on basis of the three parameters mentioned above - (pest and disease resistance and yield). Scientific attention is mostly drawn towards dry matter hence limited research has been conducted to evaluate the quality of cassava roots harvested earlier than recommended, especially for the newly released varieties. The parameter that has been studied most in research on cassava root
quality is dry matter content, whereas the roots also have other components that include carbohydrates, fiber, and ash among others as reported by Motagnac, (2009).

Cassava roots also contain micronutrients that can be exploited to improve nutrient security for the cassava growing and/or consuming communities. In recent years, consumers and food processors have shown considerable interest in foods’ nutritional quality, Shobha et al. (2012). Exploitation of micronutrients especially in cassava roots can only be fully achieved if studies are carried out to determine their levels as well as identify the crop age at which they are at peak.

It is important to note that cassava is also known to contain hydrogen cyanide that is poisonous to both humans and livestock, Bechoff et al. (2018). There is still limited information on this compound concerning its concentration in cassava roots at various stages of growth specifically for newly released KARI varieties. Hydrogen cyanide is the bound form of glucoside produced by linamarin that is toxic to both human and animals Cardoso et al. (2005). Determination of hydrogen cyanide levels will enhance consumers’ safety especially the consumers of the cassava varieties grown in coastal Kenya. Consumption of unsafe levels of hydrogen cyanide for prolonged periods has been associated with the Konzo disease which mainly affects children Topor et al. (2008). This study sought to evaluate cassava root dry matter, carbohydrate, energy, starch, fiber, ash, protein, fat, hydrogen cyanide and selected micronutrients contents in relation to crop age.

2. Materials and methods

2.1 Acquisition of raw materials

Three cassava varieties that are popular in the coastal region of Kenya were used for harvesting the experimental materials for this study. These three varieties were; Tajirika, Kibanda Meno and Karembo. Kibanda Meno is an indigenous variety that registers early maturity, high dry matter and sweetness that has led consumers to enjoy it when eating it raw, roasted or boiled Mwamachi, (2005). Kibanda Meno is also known to me more resilient in drought resistance. It is the local variety that is commonly grown alongside the improved varieties as means of risk mitigation over crop loss Wekesa et al. (2017). Though Kibanda Meno has low yield (2.02 t/acre) and susceptible to diseases as reported by Gethi et al. (2009), the coastal communities have remained persistent on its preference to grow Kibandameno Mwamachi, (2005). Kibanda Meno and Tajirika are improved varieties that were bred and released by KARI in the year 2008. These varieties were bred for pest and disease resistance and also high yields. Karembo has a yield potential of up to 27 tons per hectare and Tajirika has yield potential of up to 25 tons per hectare Muli et al. (2009). Variety Karembo has a stem that is characterized by short internodes (Muli et al. 2009) and producers have adopted it for seed multiplication, a part from the high yields. Variety Tajirika has most of its traits almost similar to those found in the local variety Kibanda Meno, apart from dry matter content that is said to be lower. Tajirika however has long roots with medium thickness that make them preferred in the fresh market Muli et al. (2009).

The varieties; were obtained from mother blocks at three Kenya Agricultural and Livestock Research Organization (KALRO) Centres. The three Centers were; Masabaha, Matuga and Mtwapa. A total of 4 healthy plants were randomly selected and harvested at 3, 6, 9 and 12 months after planting. Harvesting of roots was carried out using a hoe. The hoe was used to carefully remove top soil in order to dig out the roots while ensuring minimal bruises. A total of 3 medium sized roots were harvested from each plant. The roots were then packaged in labeled polyethylene bags per variety and per age group. The labelled roots were then put in cooler boxes for overnight transportation to the University of Nairobi for analysis in the Food Science Laboratories. The roots were prepared by washing before and after peeling, and macerating using laboratory blender. Macerated root mashes were well mixed accordingly and sampled in replicates for analysis.

2.1.1 Determination of Moisture /Dry Matter (DM) content

Moisture content determination was carried out using gravimetric method with a few modifications. About 5 g of macerated sample were weighed in crucibles and dried for 4 hours at 105 °C in an air oven as described by AOAC, (2001) method 925.10.

2.1.2 Determination of Starch Content

Cassava starch content was determined by standard methods AOAC, (2012) method 985.29, with minimal modification where filtration of roots’ mash to remove starch was done using a cheese cloth instead of a sieve with known mesh size. Before filtration, root mash had been mixed with distilled water at ratio of 2:1.

2.1.3 Determination of Energy Content

The energy content was obtained by multiplying the value of crude protein, fat and carbohydrate by factors of 4, 9 and 4 respectively as indicated by Omososili, (2014).

2.1.4 Determination of Crude Fiber

Crude fiber was determined as described by AOAC, (2000) method 985.29. A duplicate 4 g sample of root mash was boiled for 30 minutes in 25 ml of 2.04 N H₂SO₄ diluted to 200 ml with boiling distilled water. The mixture was then filtered by use of a buchner funnel slightly packed with glass wool. The collected residue was washed thrice with ethanol, followed with air oven drying at 105 °C for 2 hours then ashed at 550 °C in a muffle furnace.
2.1.5 Determination of Ash Content
Briefly 4 g sample of cassava root mash in duplicate was burnt in porcelain crucible using Bunsen burner (low flame) for 10 minutes then transferred to a Muffle furnace, ashed at 550°C for 4 hours as guided in AOAC, (1995) method 923.03

2.1.6 Determination of Crude Fat
Briefly 5 g sample was extracted using soxhlet extractor for 8 hours using 200 ml petroleum ether (40-60 °C). Crude fat content was calculated after evaporating the solvent and the residue dried in an air oven at 105 °C for 1 hour as guided by Mishra, (2017).

2.1.7 Determination of Protein
Protein content in cassava roots was determined as per AOAC, (2005) method 979.09.

2.1.8 Determination of Hydrogen Cyanide
Hydrogen cyanide determination was carried out using distillation method. Cassava roots were macerated using a laboratory blender and samples of 10 g root mash was placed into distillation flask and allowed to stand for three hours before distillation. Distillation and consequent determination of hydrogen cyanide was carried out as guided in AOAC, (2016) method 915.03.

2.1.9 Determination of Carbohydrates
Carbohydrates were determined by difference. The total of moisture content, fat, ash, protein and fibre contents were subtracted from 100 as guided in FAO, (2003)

2.2. Determination of Vitamin C
Approximately 15 ml (10%) TCA, was added into flat bottomed flask containing cassava roots mash and filtered. A total of 15 ml filtrate sample was collected. The filtrate sample was then mixed with 5 ml of 4% potassium iodide solution then titrated. The rest of procedure was followed as described in AOAC (2013) method 967.21.

2.2.1 Determination of Iron and Zinc Content
Cassava root mash sample (4g) for determining mineral Iron was ashed in a muffle furnace at 500 °C for 4 hours. Then digested by adding 10mls of 20% HCL to boiling, then filtered into 100 ml volumetric flask and topped to mark using distilled water. Using atomic absorption spectrophotometer (A.A.S) mineral iron and zinc was determined according to AOAC, (2016) method 99.10

2.2.2 Experimental Design and Data Analysis
The statistical design used in the study was Complete Randomized Design, where varieties and crop growth stage were independent variables. Data were collected on the following parameters: Hydrogen cyanide levels, Carbohydrates in, Starch, Fiber and Dry matter, protein, fat and selected micronutrients. Results from laboratory analyses were subjected to the analysis of variance (ANOVA), using Statistical Analysis System (SAS version 9.1). Means were separated using Least Significant Difference (LSD), the differences being significant when p≤0.05.

3. Results and discussion
3.1 Dry matter and starch content

![Dry Matter Content Chart](chart.png)

Figure 1: Dry matter content (%) of cassava roots as affected by crop age. The bars indicate standard error bars.

There was significant (p ≤ 0.05) interaction between variety and crop age on dry matter, starch, carbohydrate, energy, fiber, ash and hydrogen cyanide Kibanda Meno contents. While varieties Karembo and Tajirika attained the highest root dry matter content (43.42% and 41.42% respectively) at 12 months after planting, the local variety Kibanda Meno attained the highest dry matter content (44.99%), 9 months after planting (Figure 1).
There was no significant difference (p>0.05) in dry matter content for Karembo and Kibanda Meno harvested at either 6 or 9 months after planting. Tajirika harvested at 9 months after planting had 38.7% dry matter content as compared with 30.6% at 6 months. Between 9 and 12 months after planting, Karembo and Tajirika had accumulated 8.0% and 7% higher dry matter content, respectively. The dry matter content of Kibanda Meno dropped by 8% when left in the field beyond 9 months and harvested at 12 months after planting. These results indicate that farmers who use root dry matter content as the criterion for choice of cassava variety will still prefer the local variety, Kibanda Meno, since they would be able to harvest it as early as six months after planting. However, the improved varieties Karembo and Tajirika give yields of up to 27 and 25 t/ha⁻¹ respectively compared to Kibanda Meno that gives 5 to 10 t/ha⁻¹ under similar conditions and cultural treatment. Therefore, farmers who adopt the improved varieties will be better off, even though they will have to wait a little longer to start harvesting their cassava. Dry matter content of the coastal varieties is higher compared to those reported by Montagnac, (2009) and Benesi, (2004) that ranged between 35% and 38%. It is important to note that dry matter in cassava plays a major role for a variety to be accepted for both consumption and production Bechoff et al. (2018). Dry matter is also the indicator component for higher starch and carbohydrates content that are sought for to supply the daily energy requirements for the cassava growing households and the cassava growing communities. The results in this study showed a 13% drop in dry matter at 6 months after planting of variety Tajirika. Agronomists have linked such scenario with growth pattern, especially when the crop is at its maiden stage of attaining crucial biomass to support its growth and or flowers. It is well demonstrated when cassava is cut back to allow for a ratoon crop, dry matter drops to non-palatable state as the new biomass establishes. Gethi, (2009) reported higher biomass at 6 months after planting of the improved varieties. However, this remains an information gap that could be established through research.

![Figure 2: Variation of Starch content (% dry weight basis (dwb)) of cassava roots as affected by crop age. The bars indicate standard error of means.](image)

There was significant (p≤ 0.05) effect of crop age on starch content in Kibanda Meno. The starch content of Kibanda Meno increased from 68.2% to 93% (on dry weight basis (dwb)) between 3 and 9 months after planting (Figure 2). Starch content in variety Kibanda Meno reduced by 3.3% when harvested at 12 months instead of 9 months after planting. On a dry weight basis (dwb), the results showed that the three varieties evaluated in this study had starch content ranging from 68.5% to 93% at 9 months after planting. These results compared well with those reported by Mouafi et al. (2018). Varieties studied by Montagnac Montagnac et al. (2009) had starch content that correspond well with the results in the current study though they were reported on wet basis. Montagnac’s varieties had starch content range of 32-35% - reported on wet weight basis.

Kibanda Meno had the highest starch content of 93% (dwb) compared to Karembo and Tajirika that had 76% and 69% (dwb) respectively when harvested at 9 months after planting. This scenario could be due to varieties’ genetic characteristics and also as influenced by other factors including climatic conditions as postulated by Salvador Salvador et al. (2014); Bechoff et al. (2018); Burns et al. (2012). These values are relatively high in comparison to those reported by Eke et al. (2007) where 39 cassava varieties showed percent starch content that ranged between 20.2% and 31.8%. Inasmuch as the coastal region is known for poor soil fertility and harsh climatic conditions the varieties are competing well in starch build up with varieties grown under favourable conditions elsewhere. The trend in the current study also shows a consistent accumulation of starch content in roots through to 12 months after planting.
3.1.2 Proximate composition

There was significant ($p \leq 0.05$) difference in carbohydrate content accumulation for the improved varieties and Kibandameno – the local variety. The improved varieties had peak accumulation of carbohydrates at 12 months while Kibandameno had its peak at 9 months after planting. Crop age 6 to 9 months had significant ($p \leq 0.05$) effect on carbohydrate content of Kibandameno and Tajirika. Tajirika had the highest increase in this age range at 31.8%. The carbohydrate content of Karembo was 37.6% at 9 months and 40.5% (dwb) at 12 months after planting (Table 1). These results are within the range of carbohydrates contents that was reported by Richardson, (2013) who tested six mature improved varieties harvested at between 12 and 13 months after planting. The six varieties evaluated by Richardson, (2013) had carbohydrates content of between 26.3 % and 39.6 % (dwb).

However, the nutritional content of cassava depends on geographic location, variety, age of the plant and the specific plant part (root or leaves) and environmental conditions Salvador et al. (2014); Bechoff et al. (2018); Burns et al. (2012)

Crop age had significant ($p \leq 0.05$) effect that resulted in change in energy content of cassava roots between 3 and 12 months after planting. There was 17.9 %, 41.3% and 40.1% increase in energy (kcal/100 g dry weight) content, for Karembo, Kibandameno and Tajirika, respectively during this period. Variety Karembo had 11% increase in energy content from 3 to 6 months after planting while Kibandameno and Tajirika had 38% and 17.1% increase respectively over the same period. Energy content in Kibandameno increased by 3% while energy content in Tajirika roots increased by 7% between 6 months after planting and 9 - 12 months after planting, while variety Karembo added 9.4% energy content over the same period of time. These results show that energy content of coastal varieties is averagely higher compared to those varieties reported by Montagnac, (2009). At 12 months after planting energy contents of the coastal varieties were as follows: Karembo had 169.8 kcal/100 g dry weight, Kibandameno had 155.7 kcal/100 g dry weight and Tajirika had 161.2 kcal/100 g wet weight. The varieties tested by Montagnac had energy content of between 110 and 149 kcal per 100 g dry weight. This is a positive indicator that popularizing cassava varieties in the coast region can help households acquire a bigger percentage of the daily required calories. This makes them more suitable for processing whole root product.

The change in fibre content for Tajirika was not statistically significant ($p>0.05$). At 6 months after planting, the fibre content of Karembo, Kibandameno and Tajirika increased by 53.5%, 41% and 49% respectively (Table 1). However, there was a decline in fibre content by 18%, 17% and 31% between 6 and 9 months for Karembo, Kibandameno, and Tajirika, respectively. The fibre content of Kibandameno increased by 30% between 9 and 12 months after planting. Tajirika had its fibre content decrease by 9% as it matured between 9 and 12 months after planting. The results indicate that the improved varieties (Karembo and Tajirika) become less fibrous when left longer in the field to be harvested at 12 months but Kibandameno accumulates more fiber when left to reach 12 months after planting. The fibre content in the coastal cassava varieties is rather low at 0.9% to 1.3% (dwb) across the 3 varieties, as compared to results reported by Enidiok et al. (2008) who tested 7 cassava varieties from Ethiopian Agricultural Centre and found that fibre content in all of them ranged between 1.7% and 1.8%. However, Aileyegun et al. (2017) reported fibre content in cassava ranging between 0.48 and 2.59% (dwb) in their studies on gari. The less fibrous cassava roots are the more palatable and well accepted by producers, consumers and processors Burns et al. (2012); Bechoff et al. (2018), the coastal varieties therefore would compete well with other varieties at farm gate, fresh or processing markets.

Ash content in the three varieties was between 0.67 to 0.98 in variety Karembo, 0.84 to 1.29 in variety Kibandameno and 0.65 to 1.03 in variety Tajirika. (Table 1) The results showed significant ($p \leq 0.05$) interaction between crop age and ash content. The change in ash content between 3 and 6 months after planting for variety Karembo was a 23.4 % decline but crop age 6 to 9 months after planting showed a 2.7% increase in ash content. This is an indicator that the improved varieties (Karembo and Tajirika) become less fibrous when left longer in the field to be harvested at 12 months but Kibandameno accumulates more fiber when left to reach 12 months after planting. The fibre content in the coastal cassava varieties is rather low at 0.9% to 1.3% (dwb) across the 3 varieties, as compared to results reported by Enidiok et al. (2008) who tested 7 cassava varieties from Ethiopian Agricultural Centre and found that fibre content in all of them ranged between 1.7% and 1.8%. However, Aileyegun et al. (2017) reported fibre content in cassava ranging between 0.48 and 2.59% (dwb) in their studies on gari. The less fibrous cassava roots are the more palatable and well accepted by producers, consumers and processors Burns et al. (2012); Bechoff et al. (2018), the coastal varieties therefore would compete well with other varieties at farm gate, fresh or processing markets.

Ash content in the three varieties was between 0.67 to 0.98 in variety Karembo, 0.84 to 1.29 in variety Kibandameno and 0.65 to 1.03 in variety Tajirika. (Table 1) The results showed significant ($p \leq 0.05$) interaction between crop age and ash content. The change in ash content between 3 and 6 months after planting for variety Karembo was a 23.4 % decline but crop age 6 to 9 months after planting showed a 2.7% increase in ash content. This is an indicator that variety Karembo’s roots left in the field beyond 9 months after planting does not guarantee increase of nutrients. Variety Kibandameno had a significant ($p \leq 0.05$) change that was characterized with consistent increase in ash content of up 53.4 %, from 3 to 12 months. Variety Tajirika showed a similar trend with Karembo where there was a significant ($p \leq 0.05$) decline of 36.9% from 3 to 6 months after planting followed by 18.5% increase in ash content from 6 to 9 months after planting. From 9 to 12 months after planting Tajirika, however, showed 27.3% increased ash content (Table 1). However, the change in ash content for Tajirika was not statistically significant ($p>0.05$). An increase in age from 3 to 6 months decreased the ash content by 23.5% and 36.9% in the roots of Karembo and Tajirika, respectively, while the same increase in age increased the root ash content of Kibandameno by 12%. Variety Kibandameno had the highest ash content in comparison with the improved varieties. The results on improved varieties are high compared to those reported by Kalawole and Akighaba, (2010) where ash content was 0.54% (dwb) in roots harvested at 12 months and above after planting. However, Montagnac, (2009) reported ash content of 0.4 to 1.7% (dwb) from roots of assorted cassava varieties.
peak was at month 3. This conforms to the study carried out by Richardson and Benesi where six varieties planting (Table 2), this culminates to 138% increase. Variety Kibanda Meno showed a decrease of 37.8% from 3 months after planting. These results indicate a significant (p< 0.05) interaction effect of crop age and variety on protein content.

Hydrogen cyanide levels of 3.1 mg/kg and 3.6 mg/kg respectively in roots harvested at full maturity, i.e. over 12 months after planting. The results are, however, comparing well with those reported by Ubwa et al. (2015). The accepted hydrogen cyanide levels by codex standards Codex, (1989) is up to 10mg/Kg that is equivalent to 10ppm Endmemo, (2017) On the other hand hydrogen cyanide levels that were reported to be endemic with reference to Konzo disease, were between 47 and 614 mg/kg Rijsen et al. (2013); Bolhuis, (1966) as cited in Lukuyu et al. (2014) observed that Hydrogen cyanide content that is below 50 mg/kg is innocuous. The coastal varieties have protein content was at 12 months after planting. Variety Kibanda Meno had its peak protein at month 6 while Karembo’s is up to 10mg/Kg that is equivalent to 10ppm

Means followed with the same superscript in the same row are not significantly different at 5% level of significance

Fat content was shown to be low ranging between 0.2 and 0.8 % dwb (Table 2). The results of the current study showed significant (p< 0.05) interaction effect on cassava roots fat content. The variation on the coastal varieties is wider compared to 6 varieties studied by Richardson (2013), whose range of variation was between 0.2 and 0.4% (dbw) fat content. The results conform to those reported by Icabunike, et. al. (2017) who reported fat content of 0.78% for the bitter varieties and 0.27% for sweet varieties.

Change in protein content for variety Karembo, from 3 to 6 months after planting was 74.7% decrease, 4.5% decrease from 6 to 9, however protein content increased from 0.21 % to 0.50% (dwb) from 9 to 12 months after planting (Table 2), this culminates to 138% increase. Variety Kibanda Meno showed a decrease of 37.8% from 3 to 6 months after planting, 7.14% increase from 6 to 9 months after planting and a decrease of protein content of 3.33% from 9 to 12 months after planting.

Variety Tajirika showed a decrease of 42% from 3 to 6 months after planting, then an increase of 117.24% from 6 to 9 months after planting. Another increase of 22.2% protein content was shown from 9 to 12 months after planting. These results indicate a significant (p< 0.05) interaction effect of crop age and variety on protein content. Variety Karembo had the highest protein content at 3 months after planting followed by Tajirika whose highest protein content was at 12 months after planting. Variety Kibanda Meno had its peak protein at month 6 while Karembo’s peak was at month 3. This conforms to the study carried out by Richardson and Benesi where six varieties evaluated for quality showed a range of 1.20 to 2.10% protein at 12 and 13 months after planting Richarson, (2010). This shows that the popular varieties grown in coastal Kenya have lower protein content than other varieties elsewhere. It is advisable therefore that consumers supplement cassava roots dishes with protein source. Also in order to maximize on the little protein contained in cassava roots Tajirika has peak protein levels at 12 months, Kibanda Meno at 6 months and Karembo at three months after planting therefore it is advisable that harvesting of roots to be staggered accordingly.

The change in root hydrogen cyanide content between 3 and 12 months after planting was 0.12% to 9.34%, 0.12% to 5.24% and 0.13% to 4.47% for Karembo, Kibanda Meno and Tajirika respectively (Table 2). While longer period in the field from 6 to 9 months after planting had no effect on root hydrogen cyanide content in Karembo, Kibandameno and Tajirika accumulation was 22% and 37% times more cyanide over the same period of time. Longer period in the field from 9 to 12 months showed accumulation of hydrogen cyanide content in the roots of Karembo by 8%, while the same period caused 33% and 12%, reduction of hydrogen cyanide content in the roots of Kibanda Meno and Tajirika by respectively. Results in this study show that the coastal varieties had hydrogen cyanide content that range between 0.12 mg/kg to 13.00 mg/kg dry weight. The results are higher compared to results reported by Onwuka and Ogbo, (2007) whose two varieties (one improved and a local) had hydrogen cyanide levels of 3.1 mg/kg and 3.6 mg/kg respectively in roots harvested at full maturity, i.e. over 12 months after planting. The results are, however, comparing well with those reported by Ubwa et al. (2015). The accepted hydrogen cyanide levels by codex standards Codex, (1989) is up to 10mg/Kg that is equivalent to 10ppm Endmemo, (2017) On the other hand hydrogen cyanide levels that were reported to be endemic with reference to Konzo disease, were between 47 and 614 mg/kg Rijsen et al. (2013); Bolhuis, (1966) as cited in Lukuyu et al. (2014) observed that Hydrogen cyanide content that is below 50 mg/kg is innocuous.
hydrogen cyanide range of between 9.3 mg/kg and 12 mg/kg - conversion done using Endmemo (2017) convertor table. Variety Karembó however has high cyanide content across the studied crop ages. Studies by Topor et al. (2008) showed storage of fresh roots caused hydrogen cyanide levels to decline. However moisture stress on cassava roots in the field causes hydrogen cyanide level to rise - as reported by Srihawong et al. (2015). The trend shown in this study on hydrogen cyanide build up indicate a moisture stress on the roots as hydrogen cyanide was shown to rise as the roots were left longer in the field. Moisture stress is a common phenomenon in the coastal region of Kenya.

**Table 2:** Proximate composition (dry wb) of three coastal Kenya cassava varieties as affected by crop age

*Means followed with the same superscript in the same row are not significantly different at 5% level of significance.

The results of the current study showed significant (p < 0.05) interaction effect on cassava roots vitamin C content (Table 3). The three varieties registered vitamin C content that ranged from 7mg/ 100g to approximately 70mg/ 100g across the 4 crop ages studied. After determining the % change per variety Karembo showed that the change in vitamin C content in was up to 585.89% increase from 3 to 6 months after planting, after which there was a 31% reduction from 6 to 9 month after planting and then a further 26.79% reduction from 9 to 12 months after planting Variety Kibandameno had persistent decline in vitamin C content in the following trend from 3 to 6 months (796.21 %), 6 to 9 months (7.97 %) and 22.94% after planting, from 9 to 12 months after planting. Variety Tajirika had a vitamin C content increase of 445.38% from 3 to 6 months after planting. Then an increase of 23% from 6 to 9 months after planting and a decrease of 13.76% from 9 to 12 months after planting. Therefore, varieties Karembo and Kibandameno showed a decreasing trend in vitamin C content when left in the field for a period beyond 6 months after planting, while Tajirika's vitamin C content started decreasing when left in the field beyond 9 months after planting (Table 3). There was therefore significant (p< 0.05) interaction effect between vitamin C content (mg/100 g dry weight) and crop age.

The results showed substantial high content of vitamin C in all the three varieties, Karembo 64.2 mg/100g, Kibandameno 66 and mg Tajirika 69.6 mg/100g. These results are higher than those reported by Davidson et al. (2009) whose results were 14.9 to 50 mg/100g. They however compare well with those reported by Davidson et al. (2017). Salvador et al. (2014) postulates that chemical content of cassava varies depending on the plant part, climatic and environmental condition and agro - ecological location of production. Peak vitamin C content also significantly varied, Tajirika. Karembo and Kibandameno attained their highest vitamin C content at 6 months after planting. Tajirika had its highest level of vitamin C at 9 months after planting. The results indicate that cassava roots for Karembo and Kibandameno loose vitamin C when left in the field longer than 6 months after planting. The percent drop in vitamin C content from 6 to 9 months after planting was as follows; Karembo 30.9 % and Kibandameno 7.9 % when harvested at 9 months after planting instead of harvesting them at 6 months after planting. Tajirika’s vitamin C content however drops when the variety is left in the field beyond 9 months after planting (Table 3).

3. 1. 3 Variation in mineral contents

The change in variety Karembo for mineral iron content was a persistent accumulation from 3 to 6 months after planting (41.05%) and 25.23% from 6 to 9 months after planting. At 9 to 12 months after planting the results showed 12.62 % decline in mineral iron content (Table 3). Variety Kibandameno had 28.9 % decline in mineral iron content from 3 to 6 months, then had an increase of 134.98 % from 6 to 9 months after planting, then showed a decrease of 26.97 % from 9 to 12 months. Variety Tajirika showed a decrease of 46.15 % from 3 to 6 months after planting, then another decrease of 17.42 % from 6 to 9 months after planting. There was further decrease of 5.48% mineral iron content from 9 to 12 months after planting. The results therefore showed significant (p< 0.05) interaction effect on cassava roots in relation to iron content (Table 3). Kibandameno had significantly (p<0.05) higher iron content in all the crop ages compared to the improved varieties. At 3 months after planting, Kibandameno had 4.3 mg/100g dry weight iron content that indicated to be higher 14.7 % than Karembo’s iron content, that stood at 3.6mg/100g dry weight. Peak iron content was found to be at the tender crop age of 3 months after planting.
planting for the improved varieties. Karembo (3.6 mg/100 g dry weight) and Tajirika (5.3 mg/100 g dry weight), while variety Kibanda Meno had its peak iron content (7.12 mg/100 g dry weight) at 9 months after planting. These results are within the range reported by Ifeabunike et al., (2017) and Davidson et al., (2017), who reported iron content of 2.25 mg/100 g dry weight for bitter varieties and 4.0 mg/100 g dry weight for the sweet varieties. Studies carried out by Chavez et al. (2000) showed a mean iron content of 9.6 mg/100 g dry weight in cassava roots, while Montagnac’s results were at 0.3 mg/100 g dry weight to 14.0 mg/100 g dry weight Montagnac, (2009). This is however expected since cassava nutrients and/or physical characteristics are influenced by several factors as stated by Salvador et al., (2014).

Change in mineral zinc content showed of 176.32% accumulation in variety Karembo when left in the field from 3 to 6 months after planting, then there was a 60% reduction when the crop was left in the field from 6 to 9 months after planting, and a further 73.81% accumulation of mineral zinc from 9 to 12 months after planting. Variety Kibanda Meno showed 54.72% increase in mineral zinc content from 3 to 6 month after planting. There was 18.28% reduction of mineral zinc from 6 to 9 months after planting. There was 190% accumulation of mineral zinc content from 9 to 12 months after planting. Variety Tajirika showed 96.83% change from 3 to 6 months after planting. The period between 6 to 9 months after planting caused a 20.97% decline in mineral zinc content but there was 16.67% accumulation at 9 to 12 months after planting. The results of the current study also showed significant (p< 0.05) interaction effect on cassava roots in relation to zinc content (Table 3). Variety Karembo had the highest Zinc (2.1 mg/100 g dry weight) content at 6 months after planting. Tajirika and Kibanda Meno had their peak zinc content at 12 months that were 1.75 mg/100 g dry weight and 1.94 mg/100 g dry weight respectively. Tajirika’s Zinc content at the peak was 1.75 while Kibanda Meno was 1.46 mg/100 g dry weight. These results are within the range that was reported by Charles et al., (2005). His five cassava varieties had zinc content range of between 1.4 and 4.25 mg/100 g dry weight.

4. Conclusion and Recommendation
The current study concludes that the crop age has influence on cassava roots’ quality but leaving the crop in the field for longer period after planting does not warrant maximum root quality in terms of nutrient levels. At 9 months after planting, several nutrients evaluated in this study are at higher levels but the micronutrients are at higher levels between 3 and 6 months after planting. The study therefore recommends staggered harvesting of cassava roots at different crop ages but at around 9 months is best based on dry matter and starch content.
